Running title: Transcatheter closure of ductus arteriosus in early infancy
Abstract

Purpose: Transcatheter device closure of patent ductus arteriosus (PDA) is challenging in early infancy. We evaluated PDA closure in infants less than 6 months old.

Methods: We performed a retrospective review of infants less than 6 months of age who underwent attempted transcatheter device closure in our institution since 2004. To compare clinical outcomes between age groups, infants aged 6-12 months in the same study period were reviewed.

Results: A total of 22 patients underwent transcatheter PDA closure during the study period. Patient mean age was 3.3 ± 1.5 months, and weight was 5.7 ± 1.3 kg. The duct diameter at the narrowest point was 3.0 ± 0.8 mm as measured by angiography. The most common duct type was C in the Krickenko classification. Procedural success was achieved in 19 patients (86.3%). Major complications occurred in 5 patients (22.7%), including device embolization (N=1), acquired aortic coarctation (N=2), access-related vascular injury requiring surgery (N=1), and acute deterioration requiring intubation during the procedure (N=1). Two patients had minor complications (9.1%). Twenty-four infants aged 6-12 months received transcatheter device closure. The procedural success rate was 100%, and there were no major complications. The major complication rate was significantly higher in the group less than 6 months of age (P=0.045). There was a trend toward increased major complication and procedural failure rates in the younger age group (P<0.01).

Conclusion: A relatively higher incidence of major complications was observed in infants less than 6 months of age. The decision regarding treatment modality should be individualized.

Key words: Congenital heart disease, Patent ductus arteriosus, Transcatheter closure
Introduction

Patent ductus arteriosus (PDA) causes left heart volume overloading and may lead to congestive heart failure, atrial arrhythmia, or pulmonary hypertension.\(^1\) Transcatheter device closure of PDA is an established and widely accepted treatment modality in adolescents, children, and older infants.\(^1-5\) However, there is limited evidence and thus far few studies exist for early infants.\(^6-11\) The Amplatzer duct occluder (ADO) device is the globally most popular device for PDA, and it is approved to use in infants older than six months and weighing more than 6 kg, per the manufacturers. To analyze clinical outcomes and safety of transcatheter closure of PDA in early infancy, we performed a retrospective analysis of infants less than six months of age in whom transcatheter device closure was attempted. In addition, we present a comparison of the procedural outcomes between patients less than six months old and those 6-12 months old who underwent transcatheter closure of PDA in the same study period.
Materials and methods

We reviewed medical records of patients who underwent transcatheter closure of PDA at Samsung Medical Center between 2004 and 2017. PDA closure is generally indicated in patients with signs of left ventricular volume overloading. Based on literature; we included patients who had clinical symptoms of volume overload, cardiomegaly on chest radiography and left ventricular dilatation on echocardiography. However, patients with severe pulmonary hypertension due to other reasons than PDA were excluded. Among these patients, those less than six months of age at the time of the procedure were enrolled. To compare the success and complication rates between age groups, the procedural outcomes of patients 6-12 months old who underwent transcatheter device closure in the same study period were also collected. All of the procedures were performed by experienced pediatric interventional cardiologists. Institutional Review Board approval was obtained (SMC 2018-04-040-001).

1. Procedure

Informed consent was obtained from the patients’ parents before the procedure. Prophylactic antibiotic cefazolin was administered. Most of the procedures were performed under deep sedation, except for patients who were already mechanically ventilated before the procedure. A 4 French (Fr) sheath was placed in the femoral artery and vein. After collecting hemodynamic data, images of the ductus were obtained by angiography with right lateral oblique and lateral views. With the angiographic images, the ductal type and shape were determined according to the Krichenko classification. Then, the type and size of the device were chosen considering the ductal anatomy. A delivery catheter was passed through the PDA from the femoral vein to the descending aorta over a guide wire. The device was then
advanced into the delivery catheter. For the device, ADO I, Amplatzer vascular plug (AVP) II, and Cocoon PDA were used. After deployment of the device, an aortogram was obtained to evaluate residual shunts and device position. The fluoroscopy time was recorded.

2. Evaluation after implantation

Transthoracic echocardiography was conducted within 48 hours after the procedure. Then, routine follow-ups were done at one and six months after discharge. All of the complications related to the procedures were recorded. Cardiac arrest or death, hemodynamic instability, deterioration of respiration requiring mechanical ventilation during the procedure, embolization of the device, acquired coarctation requiring surgery, and vascular complications requiring surgery were classified as major complications. Mild left pulmonary artery (LPA) stenosis, blood transfusion, and transient local vascular complications such as transient loss of pulse or hematoma were classified as minor complications. Successful device deployment and absence of significant residual flow at the latest follow-up were counted as procedural success.

3. Statistics

All analyses were performed using SPSS for Windows. Measured data were expressed as mean ± standard deviation or median. Procedural outcomes for each age group were compared using a chi-square test or Fisher’s exact test. Cochran-Armitage test was used for trend analysis. A p-value < 0.05 is defined as statistically significant.
Results

A total of 22 patients less than six months of age underwent transcatheter PDA closure during the study period. Eleven patients were girls (50%). The patients' mean age was 3.3 ± 1.5 months (0.4-5.9 months), and the mean body weight was 5.7 ± 1.3 (3.6-8.3) kg. All patients had clinically significant symptoms of PDA including weight stagnation or difficulty breathing. Twelve patients (55%) had associated cardiac anomalies: atrial septal defect (N=10), ventricular septal defect (N=1), pulmonary stenosis (N=1), aortic stenosis (N=1), or aortic arch hypoplasia and right coronary artery fistula (N=1). The patient characteristics and procedural data are given in Table 1.

The mean duct diameter at the narrowest point measured by echocardiography and angiography was 3.5 ± 0.7 mm (2.2-5.0 mm) and 3.0 ± 0.8 mm (1.5-4.5 mm), respectively. Ductal types were classified based on the Krichenko classification except for three patients whose angiogram images were not available for review. The most common type was C (58%, N=11), followed by type A (32%, N=6) and type B (10%, N=2).

Out of 22 patients, transcatheter closure was successfully performed in 19 (86.3%). The median follow-up duration was 7.2 months (0.3-50.9). An immediate aortogram after deployment of the device was routinely done, and 58% (11/19) of the cases were completely closed. Echocardiography before discharge revealed that 63% (12/19) of patients had a small amount of leakage. However, complete occlusion was confirmed in all 15 cases in which follow-up echocardiography data after discharge were available. The latest data were not available for the last four cases because they were sent to regional hospitals for follow-up. The devices used in successful procedures were ADO I (16 patients; 84%); Cocoon PDA (1 patient; 5%); and AVP II (2 patients; 11%).
Among three unsuccessful cases, the first patient was one month old, weighed 4.3 kg, and had pulmonary hypertension. The ductal type was A, and the size was 2 mm at the narrowest point. A 5/4 mm ADO I was successfully implanted initially, but the device dislodged to the descending aorta after the procedure (Fig. 1). Therefore, emergent surgical removal of the device and closure of the ductus were needed. The second patient was one month old and weighed 4.0 kg. The ductal type was B, and the size was 2 mm. A 6/4 mm ADO I was implanted (Fig. 2). Device deployment led to acquired coarctation of the aorta. Surgical device removal and ductal ligation were planned. The third patient had Down syndrome and severe pulmonary hypertension with arch hypoplasia; she was three months old and weighed 5.2 kg. The ductal type was C, and the size was 2.5 mm. An implanted 6 mm AVP II device resulted in a significant pressure difference between the ascending and descending aortas (Fig. 3). Therefore, the device was retrieved immediately by the transcatheter approach.

Major complications occurred in five patients (22.7%). There was no cardiac arrest or mortality related to the procedure. There was one case of device embolization after the procedure, requiring surgical removal as described above. Out of five patients, device deployment caused significant aortic coarctation in two patients, and the device was removed as described above. An access-related major complication occurred in one patient; initial delivery of a 5/4 mm ADO was attempted with 6 Fr and 7 Fr sheaths, but advancement was not possible. Eventually, with an 8 Fr short sheath, deployment of the device was successful. However, damaged vascular tissue was identified with the removed vascular sheath, and a common iliac vein injury was detected on angiogram. Therefore, the patient underwent emergent allograft surgery. A pulmonary hypertensive crisis occurred in the last patient during the procedure. Emergent intubation and monitoring in an intensive care unit after the procedure were needed.

Two patients had minor complications (9.1%). For one patient, loss of pulse was identified
after the procedure and was completely recovered with intravenous heparinization. He also had mild LPA stenosis after device deployment. Mild LPA stenosis was identified in two patients. Flow velocity measured by echocardiography was not significant (below 2 m/sec) in both cases. No patient required a blood transfusion due to blood loss during the procedure.

We compared the success and complication rates of the less than 6 months age group with 24 infants aged 6-12 months who received transcatheter device closure in the same study period at our institute. The procedural success rate of the 6-12 months group was higher (100%), but the difference between the age groups was not statistically significant ($P=0.101$). In the less than six months age group, the major complication rate was 22.7%. In contrast, there was no major complication in the 6-12 months group; this was statistically significant ($P=0.045$).

As, infant’s bodyweight is usually doubled in first 3 months after birth. We further divided under 6 months age group to under 3 months and 3-6 months age groups. Between three age groups, only, major complication rate between under 3 months group and 6-12 months group was significantly different ($p=0.015$). But with trend analysis using linear-by-linear association test, there was a trend of increased major complication and procedural failure rates with younger age group ($P<0.01$; Table 2).
Discussion

To our knowledge, successful transcatheter closure of ductus arteriosus has been reported even in early infancy at less than six months of age, but the major complication rate was significantly higher compared to the older age infants group.

There have been a few studies that evaluated the feasibility of transcatheter closure of PDA in small infants less than 6 kg, with procedural success rates ranging from 89.7-94.3%.\(^6\)\(^-\)\(^11\) Although the patient population was heterogeneous, different inclusion criteria and different definitions of procedural success and major complications between studies make comparison difficult. In our study, the procedural success rate of infants less than six months old was 86.3%, which is comparable with previously reported studies. The slightly lower success rate in our study may have been affected by the relatively small sample size and minimal experience, considering three failed procedures occurred in the first half of all of the attempts.

Backes et al. conducted a meta-analysis of transcatheter closure of PDA during infants aged less than one year.\(^5\) The study reported a success rate of 92.2% and an overall clinically significant complication rate of 10.1%. It is noteworthy that, in the subgroup analysis, the clinically significant complication rate was two to three times greater in studies with infants weighing less than 6 kg. A UK and Ireland multicenter study reported a successful device implantation rate of 92% in small infants less than 6 kg.\(^6\) However, a major complication rate of 10%, device embolization rate of 5%, and vascular access-related complication rate of 6% led authors to conclude that careful consideration is needed before deciding upon treatment modality. Similarly, in our study, the major complication rate was significantly higher among infants less than six months of age. Backes et al. reported that younger age less than 30 days was a risk factor of major adverse event and composite failure.\(^11\) In our study, only 1 patient
was younger than 30 days and the procedure was successfully done without complication.

As small infants have relatively smaller-sized vessels, concerns about the increased risk of device protrusion into the aorta or pulmonary artery and local vascular injury are major drawbacks in expanding the application of the transcatheter approach to small infants.\(^1\) Other than the small size of the aortic isthmus, the acute angle between PDA and the aorta and the absence of aortic ampulla in PDA types B and C were hypothesized as potential factors influencing device protrusion.\(^8\) There were two cases of mild LPA stenosis and two cases of significant aortic coarctation in our study. In the aortic coarctation cases, the PDA types were B and C, respectively. Furthermore, one patient had mild arch hypoplasia. Therefore, an absence of aortic end ampulla and underlying arch hypoplasia might increase the risk of device protrusion in our study. In the aortic coarctation cases, a 6/4 mm ADO I and 6 mm AVP II were used. A miniaturized device such as ADO II additional size (AS) might be helpful in these cases but was not available at the time.\(^13\)

Device embolization is another major concern in PDA device closure in small infants. Underestimation of PDA size, unfavorable ductal anatomy, and a suboptimal device position can be causes of embolization.\(^6\) Device embolization rates in small infants less than 6 kg were reported to be 2.4–5%.\(^6,11\) Similarly, there was one case (4.5%) of device embolization in our study. Underestimation of ductal size due to spasm was thought to be the cause of embolization in our case.

To prevent major complications, case by case approach is needed considering patient’s condition, ductal anatomy, operator’s experience, appropriate device selection and availability of surgical back-up. With our experience, large vascular sheath over 7Fr should be used with caution in early infants. And, procedures in patient with unfavorable vascular anatomy like aortic coarctation should be avoided. So, thorough evaluation of patient’s anatomy with echocardiography and computed tomography is needed in advance. However,
we are expecting advances in occlude device and delivery system will help overcome these hurdles in the future.

There are several limitations in this study. Based on the manufacturer’s recommendation, we set an arbitrary cut-off of six months of age. Due to the retrospective nature of this study, the follow-up duration and interval varied between patients, and data was incomplete in some cases. Although the procedural success rates were lower in the under six months age group, the difference was not statistically significant. This may be due to the small sample size.

In conclusion, Transcatheter closure of PDA is a successful and effective treatment option for a majority of early infants. However, a relatively higher incidence of major complications was observed in infants less than six months of age. There was a trend of increased major complication and procedural failure rates with younger age group. Considering ductal anatomy, device availability, patients' clinical situations, and operators' experience, the decision of treatment modality should be individualized, and it should be done with precaution and surgical back-up.
